Search for general relativistic effects in table-top
displacement metrology

Abstract: As displacement metrology accuracy improves, general relativistic effects will
become noticeable. Metrology gauges developed for the Space Interferometry Mission,
were used to search for locally anisotropic space-time, with a null result at the $10^{-10}$ level.

1. Introduction

General relativity predicts that remotely referenced displacement metrology [1] will experience an error
accumulating at $(dL/L)/dh=0.00011 \text{ pm/m}^2$ of altitude difference. E.g., a standard at JPL (~400 m altitude)
will appear 0.15 pm longer to a client at Mount Wilson (~1800 meters). Verifying effects like this and
searching for exotic effects predicted by alternative theories has the potential to discover “new physics.”
We describe a search for anisotropy due to the gravitational field of the sun suggested by Tomozawa [2],
using pre-existing apparatus.

2. Experiment

NASA/JPL’s Space Interferometry Mission (SIM) [3,4] has motivated the development of interferometric
heterodyne displacement metrology gauges with repeatability roughly 50 pm[5]. The gauges’ linearity and
thermal stability are tested [6] in a temperature stabilized vacuum tank with a dedicated laser source, a
temperature stabilized 1.3 micron YAG coupled to two AOMs to produce two frequencies separated by 2
kHz. This experiment used two gauges: A oriented east-west and B north-south, monitoring the distance
between corner-cube retroreflectors separated by 76 +/-2 cm. A feedback system [7] maintained head
alignment with the retroreflectors. Equal length baselines made the effect of laser frequency drift common
to both gauges, making it straightforward to search for anisotropies. E.g, a non-isotropic metric would be
observed as change in the A-B length difference.

3. Results

Displacement and alignment data for both gauges, and system temperatures were recorded at 6 points/hour
from Dec 24, 2002 to Jan 23, 2003. Figure 2 shows the relative length difference (A-B) for this period.
Features such as the initial drop, 290 pm/hour rise and dip closely follow the temperature of the aluminum
optical table in the tank, indicating a slight thermal-optic asymmetry. After removing the linear trend and
applying a Hanning filter, the Fourier amplitudes of the (A-B) data were computed (figure 3).
4. Interpretation.

The data rule out the original motivation for this work: the possibility of an anisotropy order $M_{\text{Sun}}G/(c^2R)$, $R=1$ AU, correlated with sun direction. Such an effect, which would create a nm amplitude peak at 2 cpd, can be ruled out at the 0.1 nm level. Other interesting frequencies to examine are the sidereal day (1.0027 and 2.0055 cpd) and the moon’s apparent position (0.966 and 1.932 cpd, the tide frequency). Testing frequencies around 1 cpd is problematic because of diurnal effects such as temperature changes. However at 2 cpd, things are more interesting. The 130 pm peak at 1.93 cpd might be tidal effects: ground tilt, movement of vacuum tank, but the peak at 2.13 cpd is not easily explained. Neither peak is in the temperature or pointing data, ruling out these obvious explanations.

5. Conclusion

A “parasitic” Michelson-Morley like experiment was conducted, ruling out local $10^{-10}$ anisotropies. Although this limit is not competitive with recent results [8], the experiment proved interesting and helps validate SIM metrology. A possible correlation with the lunar period hints at a local “tidal” effect.

This research was carried out at the Jet Propulsion Laboratory, California Institute of Technology, under a contract with the National Aeronautics and Space Administration.
